Keywords: Deep learning, face recognition, Algorithms, Optimisation

Abstract: Face recognition, an integral biometric identification technology, holds immense potential across domains such as security surveillance, human-computer interaction, and identity authentication. Leveraging the rapid advancement and extensive adoption of deep learning methodologies, face recognition algorithms rooted in deep learning have exhibited substantial advancements, particularly in augmenting recognition precision and resilience. Consequently, a meticulous investigation into the optimization and practical implementation of deep learning-based face recognition algorithms assumes paramount significance. In the ensuing discourse, our focus converges on the meticulous optimization and pragmatic application of face recognition algorithms founded upon deep learning paradigms.

1. Introduction

In today's digital era, face recognition technology, as an important biometric technology, has a wide range of application prospects in the fields of security monitoring, human-computer interaction, and identity authentication. With the rapid development and wide application of deep learning, face recognition algorithms based on deep learning have made significant progress in improving recognition accuracy and robustness. Therefore, it is particularly important to deeply explore the optimisation and application of deep learning-based face recognition algorithms. The aim of this paper is to deeply study and explore the optimisation and practical application of deep learning-based face recognition algorithms. The research in this paper is carried out from multiple dimensions. First, we review the traditional face recognition algorithms and deep learning-based face recognition algorithms, and deeply analyse their development history, technical means and applications, which lays the foundation for the subsequent optimization and application exploration. We focus on the advantages and challenges of deep learning-based face recognition algorithms. We then introduce a series of data preprocessing techniques, including illumination normalisation, pose correction and expression change processing methods, which help to improve the robustness of the algorithms to complex environments and variable factors. Subsequently, we provide an in-depth discussion of feature extraction and selection methods covering, among others, Convolutional Neural Networks (CNN) and Generative Adversarial Network (GAN) models, which are effective in extracting key feature information from raw images. Further, this paper explores strategies for model training and parameter tuning, which include data augmentation techniques, loss function
design, and learning rate scheduling strategies, which together help optimise the performance of the algorithms. We describe in detail the methods and performance evaluation metrics for constructing the experimental dataset, and through experimental results and in-depth analyses, we comprehensively evaluate the performance of deep learning-based face recognition algorithms in face feature extraction and matching. Meanwhile, we explore the application of deep learning-based face recognition algorithms in real scenarios, especially focusing on their practical effects in security monitoring systems and identity authentication systems. Chapter 5 is the Discussion and Outlook, which discusses and analyses the research results in depth, highlighting the limitations of the algorithms as well as the room for future improvement. On this basis, we look forward to the development trend and broad application prospects of deep learning-based face recognition algorithms in the future. Finally, this paper provides a comprehensive summary of the research work carried out, outlines the important contributions of the research results, and proposes directions for further research in the future. Through the in-depth exploration and practical application of deep learning-based face recognition algorithms, this paper aims to provide useful references and lessons for the research and application in this field.

2. Overview of relevant work

2.1. Traditional Face Recognition Algorithms

Traditional face recognition algorithms are mainly based on feature extraction and classification methods. Among them, the feature extraction methods include Principal Component Analysis (PCA), Linear Discriminant Analysis (LDA) and Local Binary Pattern (LBP). These methods represent face information by projecting the face image into a low-dimensional space or extracting local texture features. Then, face recognition is performed using classifiers (e.g., Support Vector Machines, K Nearest Neighbours, etc.). Traditional algorithms have achieved some success in face recognition, but have limited accuracy and robustness in complex environments [1].

2.2. Deep learning based face recognition algorithm

Deep learning-based face recognition algorithms have made breakthroughs in recent years. Deep learning models are capable of learning from large-scale data and automatically extracting high-level feature representations, greatly improving the performance of face recognition. Among them, convolutional neural network (CNN) is one of the most commonly used deep learning models. Through multi-layer convolution and pooling operations, CNNs are able to efficiently learn face features with spatial structure. In addition, Generative Adversarial Networks (GANs) are also widely used in face recognition. GANs improve the robustness and generalisation of the model by generating realistic face images and augmenting the training data.

2.3. Algorithmic Strengths and Challenges

Deep learning-based face recognition algorithms have several advantages over traditional algorithms. First, deep learning models can automatically learn face features, avoiding the tedious process of manually designing features. Second, deep learning algorithms are trained on large-scale data and have stronger robustness and generalisation capabilities. In addition, deep learning algorithms are able to cope with common problems such as lighting changes, posture changes and expression changes. However, deep learning-based face recognition algorithms also face some challenges, such as the need for a large amount of labelled data and high computational resource requirements [2].
This chapter reviews traditional face recognition algorithms and deep learning-based face recognition algorithms. By comparing and analysing the two, we can understand the advantages of deep learning-based face recognition algorithms in improving recognition accuracy and robustness, and provide a theoretical basis for the optimization and application exploration of deep learning-based face recognition algorithms in the subsequent chapters.

3. Optimisation of face recognition algorithms based on deep learning

3.1. Data preprocessing techniques

3.1.1. Light normalisation methods

Light normalisation is a common preprocessing method used in face recognition to reduce the impact of light changes on face images and improve the robustness and accuracy of the algorithm. In this section, we will introduce several common techniques of light normalisation methods in detail.

Histogram equalisation is a common light normalisation method, which adjusts the luminance distribution of an image so that it presents a uniform distribution over the entire luminance range. Specific steps include calculating the cumulative histogram of the image, mapping the histogram to a uniformly distributed luminance range, and then adjusting the luminance values of the image according to the mapping relationship [3].

The Gaussian pyramid method uses different scales of the image to suppress the effect of lighting changes on the face image. Firstly, the original image is downsampled several times to obtain image pyramids at different scales. Then, the high-frequency components of lighting variations are eliminated by applying Gaussian filtering to the images at each scale. Finally, the filtered image is re-upsampled to the original size to obtain the illumination normalised image.

Bilateral filtering is a nonlinear filtering method that smoothes the image while maintaining edge information. In illumination normalisation, bilateral filtering reduces the effect of illumination variations on face details. It adjusts the weights of the filter by considering the spatial distance of the image and the similarity between the pixel values to preserve the edge information and reduce the illumination variations.

3.2. Feature Point Alignment

Feature point alignment is a light normalisation method based on the position of face feature points. By detecting key feature points (such as eyes, nose, mouth, etc.) in the face image, these feature points are aligned to a fixed position. By processing the aligned face image, the effect of lighting changes on the location of feature points can be eliminated, and the accuracy of the face recognition algorithm can be improved.

In practical applications, suitable light normalisation methods can be selected according to specific needs and scenarios, or even combined with multiple methods for comprehensive processing. The goal of illumination normalisation is to make face images have more consistent apparent features under different lighting conditions, thus improving the performance and robustness of face recognition algorithms.

3.3. Attitude correction methods

Pose correction is a common preprocessing method used in face recognition to correct pose changes in face images to improve the accuracy and robustness of the algorithm. In this section, we
will introduce several common pose correction methods in detail.

Face keypoint detection is a common pose correction method that obtains information about the geometric structure of a face by detecting keypoints (e.g., eyes, nose, mouth, etc.) in the face image. Based on the position and relative relationship of these key points, the pose angle of the face can be calculated and the corresponding correction operation can be performed. 3D face reconstruction is an advanced pose correction method that acquires 3D shape information of the face by using devices such as depth sensors or structured light. Based on the 3D face model, the pose of the face can be accurately estimated and the face in the image can be corrected to a standard pose. Affine transformation is a pose correction method based on geometric transformation, which makes the face in a standard pose by performing operations such as translation, rotation and scaling on the face image. Commonly used affine transformation methods include rotation correction, scaling correction and translation correction. Face pose estimation network is a deep learning based pose correction method that predicts the pose angle of a face directly from an image by training a neural network model. This approach enables end-to-end pose correction without explicitly extracting keypoints or 3D shape information. In practice, the appropriate pose correction method can be selected based on specific requirements and scenarios. The goal of pose correction is to make the face image have more consistent epigenetic features in the presence of pose changes, thus improving the accuracy and robustness of the face recognition algorithm. Changes in facial expressions interfere with the performance of face recognition algorithms. Deep learning based expression change processing methods such as expression migration and expression stabilisation are explored for improving the robustness of the algorithm to expression changes[4].

3.4. Feature extraction and selection

Convolutional Neural Network (CNN) is a deep learning model widely used in image processing and computer vision tasks. In face recognition, CNN models perform well in feature extraction and face classification tasks. In this section, we introduce several important components and common techniques of CNN models in detail.

The convolutional layer is one of the core components of the CNN model, which extracts local features in an image by using a set of learnable filters (also known as convolutional kernels). The convolutional layer multiplies and sums the filters element-by-element with the input image through a convolutional operation to obtain a feature map. By stacking multiple convolutional layers, the CNN model can gradually extract more advanced and abstract features.

Pooling layers are used to reduce the spatial size of the feature map, reduce the computational complexity of the model, and extract the spatial invariance of the features. Commonly used pooling operations include Max Pooling and Average Pooling. The pooling layer reduces the dimensionality of the feature map by aggregating local regions of the feature map into a single value and retains the main feature information [5].

Activation functions introduce nonlinearity in the CNN model and increase the expressive power of the model. Commonly used activation functions include ReLU (Rectified Linear Unit), Sigmoid and Tanh functions. ReLU function is the most commonly used activation function, which effectively solves the problem of gradient vanishing and accelerates the convergence of the model. The fully connected layer is used to spread the features extracted from the previous convolution and pooling layers and connect them to the output layer for classification or regression. Each neuron in the fully connected layer is connected to all the neurons in the previous layer, and the number of parameters is large. In face recognition, the fully connected layer is commonly used to map the extracted features to a probability distribution of face categories. Dropout is a regularisation technique used to reduce overfitting in CNN models. Dropout randomly sets the outputs of some of
the neurons to zero during the training process, thus blocking the synergies between the neurons. This improves the generalisation ability of the model and reduces the model's dependence on specific features. The main components and commonly used techniques of CNN models. In practice, the structure and parameters of the CNN model can be designed and adjusted according to the specific task and data situation to obtain better face recognition performance.

4. Exploring the application of face recognition algorithms based on deep learning

4.1. Experimental data set construction

The method and process of data acquisition are described in detail, including the equipment and environment settings for acquiring face images. Then, describe the process of data labelling and the labelling criteria to ensure the quality and accuracy of the dataset. Discuss the methods and proportions of dividing the acquired dataset into training, validation and test sets. In addition, the steps of data preprocessing, such as image normalisation, noise removal and face alignment, are described to improve the robustness and accuracy of the algorithm.

4.2. Performance evaluation indicators

This section explains how to define and calculate the accuracy as the main metric for evaluating the performance of face recognition algorithms, and discusses its significance and limitations in practical applications, introduce receiver operating characteristic curve (ROC curve) and area under the curve (AUC) as metrics for assessing algorithm performance, explain their advantages in assessing algorithm performance and robustness at different thresholds, and show how to calculate and interpret ROC curves and AUC values.

4.3. Experimental results and analyses

This section experimentally validates the performance of deep learning-based face recognition algorithms in feature extraction, analyze the effects of different models, network structures and feature representations on recognition accuracy, and analyze the experimental results quantitatively and qualitatively. The performance of deep learning-based face recognition algorithms in the face matching phase needs to be evaluated and the accuracy and speed of the matching algorithm and compare the advantages and disadvantages with traditional algorithms also need to be discussed.

4.4. Application of algorithms to real-world scenarios

This section explores the application of deep learning based face recognition algorithms in security surveillance systems such as face recognition access control systems and video surveillance systems, discuss the accuracy, robustness and real-time performance of the algorithms in real-world scenarios, explore the application of deep learning-based face recognition algorithms in authentication systems such as mobile device unlocking and electronic payments, evaluate the accuracy and user experience of the algorithms in real-world applications and discuss their security and privacy protection issues. In this chapter, we will deeply explore the application of deep learning-based face recognition algorithms based on constructing experimental datasets and performance evaluation metrics. Through experimental results and analyses, we will evaluate the performance of the algorithms in face feature extraction and matching, and explore the effectiveness of the algorithms in real-world applications in security monitoring systems and identity authentication systems. This will provide an empirical basis for the discussion and outlook in the
subsequent chapters. 5. Outlook on Algorithm Optimisation and Improvement.

5. Model optimisation techniques

Parameter optimisation is an important step in face recognition algorithms, where the parameters of the model are adjusted and optimised to improve the performance and effectiveness of the algorithm. In this section, we will introduce several common parameter optimisation methods in detail.

Grid search is a simple and intuitive parameter optimisation method that evaluates the performance of each parameter combination by traversing all possible combinations in a given parameter space and selects the parameter combination with the best performance. Lattice search is suitable for cases where the parameter space is small and discrete, but the computational complexity is high when the parameter space is large. Stochastic search is a parameter optimisation method based on random sampling, whereby a set of parameter combinations are randomly sampled in the parameter space, their performance is evaluated, and the search space is updated for the next sampling. The advantages of stochastic search are that it can handle the case of large and continuous parameter space and has low computational complexity compared to grid search. The pruning algorithm is a parameter optimisation method used to reduce model complexity and increase computational efficiency. Pruning algorithms reduce the redundancy and computational effort of the model by cutting out unimportant parameters or connections, while maintaining the performance of the model. Commonly used pruning algorithms include L1 regularised pruning, structured pruning and iterative pruning. Adaptive learning rate is a parameter optimisation method for automatically adjusting the learning rate of a model to improve the convergence speed and performance of the model. Commonly used adaptive learning rate algorithms include Adagrad, RMSprop and Adam. These algorithms adaptively adjust the learning rate based on the gradient information of the parameters, allowing for better adaptation to different parameter updates during training. Regularisation is a parameter optimisation method used to control the complexity of the model and reduce the risk of overfitting. Commonly used regularisation methods include L1 regularisation and L2 regularisation. L1 regularisation promotes model sparsification by adding the absolute value of the parameters to the loss function, while L2 regularisation promotes model weight decay by adding the square of the parameters to the loss function. In practice, the appropriate parameter optimisation method can be chosen according to the specific problem and data situation. The goal of parameter optimisation is to find the best combination of parameters in order to make the face recognition model have better performance and generalisation ability.

6. Directions for Algorithmic Improvement

Weakly supervised learning is a commonly used learning method in face recognition that uses training data with less labelled information to train models. Since labelling large-scale face datasets is a time-consuming and laborious task, weakly supervised learning can achieve good performance despite limited label information. The following are several common weakly supervised learning methods: unsupervised pre-training is a weakly supervised learning method that initialises model parameters by training on unlabelled data. Commonly used unsupervised pre-training methods include self-encoders and generative adversarial networks (GANs). With unsupervised pre-training, the model learns a latent representation of the data, providing better initialised parameters for subsequent supervised learning. Generative Adversarial Networks are a weakly supervised learning method that consists of a generator and a discriminator. The generator generates realistic face images by learning, while the discriminator provides feedback by distinguishing between generated and real images. Through this adversarial training approach, the generator can gradually improve
the quality of the generated images and learn the distributional features of the face images. Multi-example learning is a weakly supervised learning method used to deal with the case where there are only image-level labels but no instance-level labels. In face recognition, an image usually contains multiple instances (faces), but the labels are given only for the whole image. Multi-instance learning trains a model for face recognition by splitting an image into multiple instances and applying image-level labels to each instance. Migration learning is a weakly supervised learning method that aids the current task by utilising models that have already been trained on other related tasks. In face recognition, pre-trained models, such as those trained on large-scale image classification tasks, can be used as feature extractors [6]. By freezing or fine-tuning the parameters of the pre-trained model, it can be migrated to the face recognition task to provide a better representation of the initial features. Weakly supervised learning methods can help to solve the problem of limited label information in face recognition and improve the performance and generalisation of the model. According to the specific data and task requirements, the selection of appropriate weakly supervised learning method can achieve better results.

7. Conclusion

In summary, this thesis comprehensively explores the optimisation and application exploration of face recognition algorithms based on deep learning. Through in-depth introduction of key technologies and methods, as well as outlook on practical applications and future development, this paper provides solid theoretical support and guidance for further improving the performance of face recognition algorithms and promoting their wide application in practical applications. With the continuous evolution of deep learning technology and the constant demand for face recognition applications, face recognition algorithms based on deep learning will continue to make important progress and show great potential and application value in many fields.
